## Building a Decision Tree: Takeaways 🖻

by Dataquest Labs, Inc. - All rights reserved © 2020

## **Syntax**

• Using Python to calculate entropy:

```
def calc_entropy(column):
    """

Calculate entropy given a pandas series, list, or numpy array.
    """

counts = numpy.bincount(column)

probabilities = counts / len(column)

entropy = 0

for prob in probabilities:
    if prob > 0:
        entropy += prob * math.log(prob, 2)

return -entropy
```

• Using Python to calculate information gain:

```
def calc_information_gain(data, split_name, target_name):
    """

Calculate information gain given a data set, column to split on, and target.
    """

original_entropy = calc_entropy(data[target_name])
column = data[split_name]
median = column.median()
left_split = data[column <= median]
right_split = data[column > median]
to_subtract = 0
for subset in [left_split, right_split]:
    prob = (subset.shape[0] / data.shape[0])
    to_subtract += prob * calc_entropy(subset[target_name])
return original_entropy - to_subtract
```

-Finding the best column to split on:

```
def find_best_column(data, target_name, columns):
    """

Find the best column to split on given a data set, target variable, and
list of columns.
```

• Applying a function to a data frame:

```
df.apply(find_best_column, axis=0)
    information_gain = calc_information_gain(data, col, "high_income")
```

## $\textbf{Concepts} \textbf{``formation\_gains.'} \textbf{ append (information\_gain)}$

highest\_gain\_index = information\_gains.index(max(information\_gains))

Pseudocode is a piece of plain-text outline of a piece of code explaining how the code
 highest gain = columns[highest gain index]
 works. Exploring the pseudocode is a good way to understand it before tying to code it.
 return highest\_gain

• Pseudocode for the ID3 algorithm:

```
def id3(data, target, columns)
    1 Create a node for the tree
   2 If all values of the target attribute are 1, Return the node, with
label = 1
   3 If all values of the target attribute are 0, Return the node, with
label = 0
   4 Using information gain, find A, the column that splits the data best
    5 Find the median value in column A
    6 Split column A into values below or equal to the median (0), and
values above the median (1)
    7 For each possible value (0 or 1), vi, of A,
        Add a new tree branch below Root that corresponds to rows of data
where A = vi
        Let Examples(vi) be the subset of examples that have the value vi
for A
         Below this new branch add the subtree id3(data[A==vi], target,
   10
columns)
   11 Return Root
```

- We can store the entire tree in a nested dictionary by representing the root node with a dictionary and branches with keys for the left and right node.
- Dictionary for a decision tree:
